ABSTRACT

Laser-initiated stress waves are reflected from tissue boundaries, thereby inducing tensile stresses, which are responsible for tissue damage. A self-consistent model of tissue failure evolution induced by stress wave propagation is considered. The failed tissue is represented by an ensemble of spherical voids and includes the effect of nucleation, growth and coalescence of voids under stress wave tension. Voids nucleate around impurities and grow according to an extended Rayleigh model that includes the effects of surface tension, viscosity and acoustic emission at void collapse. The damage model is coupled self-consistently to a one-dimensional planar hydrodynamic model of stress waves generated by a short pulse laser. We considered the problem of a bipolar wave generated by a short pulse laser absorbed on a free boundary of an aqueous system. The propagating wave includes a tensile component, which interacts with the impurities of exponential distribution in dimension, and an ensemble of voids is generated. For moderate impurity density ($-10^5 \text{ cm}^{-3}$) void growth reduces the tensile wave component and causes the pressure to oscillate between tension and compression. For low impurity density ($-10^6 \text{ cm}^{-3}$) the bubbles grow on a long time scale (5-10 μsec) relative to the wave interaction time ($-100 \text{ nsec}$). At later times the growing bubbles interact with each other causing pressure oscillations between tension and compression, with an average compression pressure below 1 bar. This effect increases considerably the bubble lifetime consistent with experiments. At the collapse stage small bubbles collapse earlier and induce pressures, which reduce the collapse time of the larger bubbles.

Keywords: stress wave, material failure, bubble, void, simulation

1. INTRODUCTION

In many medical applications laser-initiated stress waves induce tensile waves, which are responsible for tissue damage. Tensile stresses are generated from laser deposition on tissue boundaries and from diffraction of stress waves while propagating inside tissues.1-3 The purpose of this paper is to study the mechanisms involved in the process of tissue damage. The damage can be divided into the following stages: nucleation, growth and coalescence.4-5 The damage starts by the nucleation of an ensemble of voids around existing impurities induced by tensile stresses. The growing voids can affect the stress wave propagation. At later times the voids can interact with each other through the system pressure affecting their dynamics and lifetime.1 Thus a self-consistent model coupling stress wave propagation and void evolution is required.
We consider a bipolar wave generated on a free boundary by a short pulse laser in an aqueous system. The system is described by a one-dimensional hydrodynamic code coupled to an ensemble of impurities of exponential shape in size and nucleating a distribution of voids. The voids grow as spherical bubbles according to an extended Rayleigh model based on the Kirkwood-Bethe hypothesis.\(^6\) Two typical densities are defined in the liquid: an average density between the voids and the liquid affecting mainly the hydrodynamic motion, and a local density of the liquid affecting the thermodynamic variables as pressure through the equation of state (EOS). The evolving voids reduce the tension in the system and may cause even local compression, which induces pressure oscillation and affects the void growth. The pressure in the system is highly sensitive to density variations. Thus the growing bubbles interact with each other long before they reach the coalescence stage through density variations and pressure changes.

We find that for moderate impurity densities (\(-10^8 \text{ cm}^{-3}\)) the void growth reduces the stress wave tension and imposes oscillation between tension and compression. For low impurity density (\(-10^6 \text{ cm}^{-3}\)) voids growing on a microsecond time scale interact with each other through the variation in the density and pressure. This interaction causes the system to reach an average compression pressure below 1 bar and increases the bubble lifetimes by almost a factor of 2. This result is consistent with experimental results obtained by Paltaux and Schmidt-Kloiber.\(^1\) We further find that small bubbles collapse earlier and cause an increase in pressure oscillations and a reduction in the larger bubble lifetimes.

The paper is organized as follows: Section 2 discusses the evolution model of an ensemble of voids. Section 3 presents the hydrodynamics of the system in the presence of evolving voids. Section 4 presents the computational results, and concluding remarks are given in Section 5.

2. EVOLUTION MODEL OF AN ENSEMBLE OF VOIDS

We consider a short pulse laser absorbed on a free boundary of an aqueous liquid. A bipolar stress wave is generated from an instantaneous deposition of the laser energy and includes compression and tensile components. The tensile component acts on the system and generates a distribution of spherical bubbles or voids around the embedded ensemble of impurities.\(^4\) In the following we consider the nucleation, growth and coalescence of the ensemble of voids. In a real tissue the growing voids reduce the tissue strength and may coalesce to produce a complete fracture in the tissue.

2.1 Nucleation

We consider a distribution of impurities acting as nucleation centers. The impurities have an exponential distribution in dimension,\(^4\)

\[
n( R ) = \frac{n_0}{R_i} \exp\left(-R / R_i\right)
\]

where \( n \cdot dR \) is the number of impurities per unit volume with radius \( R \) in the range \( dR \), \( n_0 \) is impurity number density and \( R_i \) is a dimensional parameter of the distribution. In general it is possible to consider other types of impurity distribution. Typical values are \( n_0 \sim 10^5 \sim 10^8 \text{ cm}^{-3} \).
and \( R \approx 0.1 - 2 \mu m \). The surface tension pressure limits the nucleation threshold \( 2\sigma / R \), where \( \sigma \) is the surface tension parameter. In water \( \sigma = 70 \ erg/cm^2 \) and for tensions larger then \( 10 \text{ bar} \) voids nucleate around impurities with radius \( R > 0.15 \ \mu m \).

### 2.2 Growth

The voids grow as spherical bubbles around the impurities according to an extended Rayleigh model based on the Kirkwood-Bethe hypothesis. The ordinary differential equation for the bubble radius \( R \) is,

\[
R \dot{U} (1 - M) + \frac{3}{2} U^2 (1 - M) = \Delta H (1 + M) + \frac{R}{C_s} \Delta \dot{H} (1 - M),
\]

where \( U = \dot{R} \) is the bubble boundary velocity, \( M = U / C_s \) is the Mach number and \( C_s \) is the adiabatic sound speed. The enthalpy difference \( \Delta H \) is given by,

\[
\Delta H = H(R) - H_a = \int_{P_a}^{P(R)} \frac{dP}{\rho},
\]

where the enthalpy \( H(R) \) and the pressure \( P(R) \) are on the bubble boundary, the enthalpy \( H_a \) and the ambient pressure \( P_a \) are far from the bubble boundary. The enthalpies can be written as,

\[
H(R) = (\varepsilon + \frac{P}{\rho})_{r=R}, \quad H_a = (\varepsilon + \frac{P}{\rho})_{r=a},
\]

where \( \varepsilon \) is the energy per unit mass and \( \rho \) the density. The ambient pressure \( P_a \) is taken as the local and time dependent pressure obtained from the hydrodynamic simulation. The pressure \( P(R) \) on the bubble boundary depends on the pressure \( P_b \) inside the bubble, the surface tension \( \sigma \), and the viscosity \( \eta \),

\[
P(R) = P_b(R, S_b) - \frac{2\sigma}{R} - 4\eta \frac{U}{R}.
\]

where for water \( \eta = 10^{-2} \ erg \cdot sec/cm^3 \). The surface tension and the viscosity impose a threshold pressure for void nucleation.

The first term on the right of eq.(2) depends on the difference between the pressure inside the bubble and the ambient pressure. For small density changes one obtains from eq.(3), \( \Delta H = (P(R) - P_a) / \rho \) and by inserting it into eq. (2) we get a more familiar form of the extended Rayleigh equation, but less accurate. The second term on the right depends on the rate of change of the enthalpy and presents the acoustic emission by the bubble. Equation (2) can be applied for large acoustic emission with Mach number up to \( M \approx 1 \).
When the bubble grows under tension, the pressure inside the bubble is reduced almost to zero. But in the collapse stage of the bubble its volume is limited by the compressibility of the impurity inside the bubble. This situation can be presented by applying inside the bubble a Maxwell constructed equation of state (EOS).\textsuperscript{10} In the region outside the bubble where tensile wave can exist a Van der Waals EOS is selected.\textsuperscript{10} In the following simulations the EOS of water is used inside and outside the bubble. The expansion of the bubble is adiabatic. Thus adiabats can be generated for the inside and outside of the bubble, based on the initial condition after the heating of the system by the laser. The adiabats are presented for a given entropy $S_0$ in a table of pressure, temperature and energy per unit mass as a function density. The adiabats are used to describe the bubble expansion in eq.(2).

2.3 Coalescence

The growing bubbles interact with each other by changing the liquid density or pressure around them. When the void area can be linked together a fracture in the system is obtained. According to the percolation theory this happens for a relative area of $\theta_{AC} = 0.4$.\textsuperscript{11} We apply a simplified criterion for fracture according to the relative void volume. We assume that the void volume is related to the void area as a 3/2 power and select the fracture criteria for a relative void volume larger than the value $\theta_{VC} = 0.25$.

3. SELF CONSISTENT HYDRODYNAMICS AND DAMAGE EVOLUTION

In the hydrodynamic model, the liquid system including the voids behaves as a porous material with an average density $\rho_\text{av}$, that differs from the local liquid density $\rho$. The two densities are related by

$$\rho = \rho_\text{av} \frac{(1 - \theta_\text{v0})}{(1 - \theta_\text{v})}$$  \hspace{1cm} (6)

where $\theta_\text{v}$ is the local relative void volume, $\theta_\text{v0}$ is the initial relative volume of the impurities and at $t=0$ we have $\rho = \rho_\text{av}$. The hydrodynamic computations are done with $\rho_\text{av}$, while the thermodynamic quantities as pressure, heat capacity and sound speed are calculated using the EOS according to the local fluid density $\rho$. The increase in the void volume causes an increase in the liquid density $\rho$ relative to the average density $\rho_\text{av}$, which reduces the tension in the system. This couples the hydrodynamic motion to the void evolution. The sensitivity of pressure to density variations is high while other thermodynamic quantities, as heat capacity and sound speed, are weakly sensitive to density changes.

The ensemble of impurities is represented by $N$ initial radii $R_i(0)$ at time $t=0$. The radii $R_i(t)$ evolve according to the extended Rayleigh model as in eq.(2), depending on the local hydrodynamic pressure $P_n$. Other void radii in the ensemble are obtained by linear interpolation.
from the calculated $R_i(t)$. This procedure is used to calculate the relative void volume $\theta_V(t)$. The thermodynamic variables such as pressure, temperature and energy density are calculated inside and outside the bubbles based on the EOS adiabats. The adiabat table for the pressure, density and energy density are obtained for various densities in the beginning of the computation from knowing the initial entropies inside and outside the bubble.

At the end of every time step and in every spatial hydrodynamic zone, the bubble radii and the relative void volume $\theta_V(t)$ are calculated based on the local hydrodynamic pressure. In the following time step $\theta_V(t)$ is used to transform $\rho_\infty$ to the liquid density $\rho$ according to eq.(6). While the density $\rho$ and the temperature $T$ are included in the iterations, $\theta_V(t)$ is taken from the previous time step to avoid numerical fluctuations.

In the coalescence stage when $\theta_V(t) > \theta_{V_c}(t)$, the system is locally fractured and the bubbles return to their initial distribution around the impurities. The expansion in this stage is with zero pressure and conserved energy. When compression is attained, fractures can heal. Voids can be regenerated when tensile stresses are returned. In the following computation we do not enter to the coalescence stage. This stage is left for future work and further extension.

It is important to compare between the damage model based on a rate equation model as considered in Ref.(5) and our detailed Rayleigh model for bubble evolution. This will be done in future work.

### 4. RESULTS AND DISCUSSION

We consider here the simulation of a propagating stress wave interacting with an ensemble of spherical voids that nucleate and grow around a distribution of impurities. A short pulse laser is absorbed on a free boundary of an aqueous liquid system and a propagating bipolar stress wave is generated including compression and tension components. The laser energy is deposited in the system with an absorption length $l=100 \mu m$, heating the system from its initial temperature $T_0 = 20^\circ C$. The initial ambient pressure of the system is 1 bar. The tensile component interacts with the ensemble of impurities and nucleates a distribution of growing voids. We consider an exponential distribution of impurities of the form of eq.(1), where the parameter $R_i = 0.5 \mu m$. We select five groups of impurities ($n=5$) with initial radii $R_i=0.3, 0.5, 0.7, 1.0, \text{ and } 1.5 \mu m$. The growth of other bubbles is obtained by interpolation from the selected five bubble groups. We find that the results are not sensitive to an increase in the number of impurity groups. We use a Van der Waals type equation of state (EOS) of water for the liquid system including tension. The EOS is based on the NBS Steam Tables. This EOS is consistent with a sound speed $c_s = 1.49 \cdot 10^5 \text{ cm/sec}$ and a Gruneisen coefficient $\Gamma = a + bT$ for temperature $T$ below $100^\circ C$, where $a=0.053, b=0.0037, T$ is in $^\circ C$ and $C_v=3.8 \text{ J/(g }^\circ C)$. The EOS applied in the Rayleigh expansion model [eq.(2)] for the bubble interior is a Maxwell constructed water EOS, with almost zero pressure under tension above its initial volume and almost incompressible under compression below its initial volume.
4.1 Short time scale evolution

Figure (1a) shows the stress wave pressure as a function of distance $x$ from the free surface at times 50, 150, and 250 nsec and for very low impurity concentration $n_0 = 0$. The bipolar wave is propagating almost unaltered through the system. Figure (1b) considers the stress wave propagation for a moderate impurity density $n_0 = 10^8 \text{ cm}^{-3}$. As the wave propagates inside the system the void growth imposes a reduction in the tensile component and causes the pressure to oscillate between tension and compression. The pressure oscillations are related to the density variation while the voids are changing their volume.

Figure (2) shows a time dependent comparison of the stress wave pressure for densities $n_0 = 0, 10^5, 10^8$ and $10^9 \text{ cm}^{-3}$ at $x=220 \mu\text{m}$. The increase in impurity density to $10^9 \text{ cm}^{-3}$ almost completely screens the tensile component on the time scale of stress wave propagation. The screening of the stress wave for densities below $n_0 = 10^2 \text{ cm}^{-3}$ is small.

Fig. 1. Pressure vs distance for (a) impurity density $n_0 = 0$ and (b) $n_0 = 10^8 \text{ cm}^{-3}$ at times $t = 50, 150, 250 \text{ ns}$.  

183
Fig. 2. Pressure vs time for impurity densities \( n_0 = 0, 10^5, 10^6 \text{ and } 10^8 \text{ cm}^{-3} \) at a distance of 220 \( \mu \text{m} \) from the free surface.

Figure (3) shows the relative bubble volume \( \theta_r \) normalized to its maximum value as a function of distance from the free boundary for impurity densities \( n_0 = 0, 10^6, 10^7 \text{ and } 10^8 \text{ cm}^{-3} \) at time 500 ns. As the impurity density increases the bubble volume is further reduced toward the inside part of the system. This is caused by the screening of the tensile component of the propagating stress wave by the impurities. As the impurity density increases the maximum void volume increases, but less than linearly due to bubble interactions.

Fig. 3. The bubble relative volume normalized to its maximum value vs distance for impurity densities \( n_0 = 0, 10^6, 10^7 \text{ and } 10^8 \text{ cm}^{-3} \) at time 500 ns.
4.2 Long time scale evolution

In this section we consider evolution on time scales of the order of the bubble lifetimes. Figure (4) shows the bipolar wave pressure and a selection of bubble radii with initial values of $R_i=0.3, 0.5, 0.7, 1.0, 1.5 \ \mu m$ as a function of time for very low impurity concentration, $n_o = 0$ for a distance $x=220 \ \mu m$. The bubbles grow without interaction and collapse on a time scale of about 6 \mu sec. The collapse is due to the 1 bar ambient compression pressure in the aqueous system. The collapse time is similar for the various radii and weakly depends on the propagation distance $x$. The bubbles with different initial radii look similar because the tensile component acts on a long time of 100 nsec, expanding the bubbles to radii of about 10\mu m, which are much larger than the their initial radii.

![Diagram of pressure and bubble radii](image)

Fig. 4. Pressure/10 and bubble radii with initial values $R_i=0.3, 0.5, 0.7, 1.0, and 1.5 \ \mu m$ vs. time for impurity densities $n_o = 0$ and distance $x=220 \ \mu m$.

Figures (5a) and (5b) show mutual influence of the stress wave and bubble growth for impurity density $n_o = 10^6 \ cm^{-3}$ at distances of $x=220, 340\mu m$. The growing bubbles interact with each other causing pressure oscillations between tension and compression. These oscillations cause the system to reach an average compression pressure below 1 bar, thus increasing the bubble lifetimes. Bubble lifetime is delayed in fig. (5a) up to 10 \mu sec which is almost by a factor of 2 longer than the non-interacting case in fig. (4). This result is consistent with the experimental results. Bubbles with initial smaller radii collapse earlier and there is a larger spread in bubble collapse time for the various bubble radii. In fig. (5b) we find that for larger distances, as $x=340 \ \mu m$, the collapse times of the smaller bubbles is reduced and the spread of the collapse times for various radii is increased.

To follow the oscillatory nature of the pressure in the system while the bubbles are growing and collapsing, we show in fig. (6a) the pressure on a larger scale (bar). Pressure oscillations between tension and compression of several bars are seen as a function of time, causing the system to reach an average compression pressure below 1 bar, thus increasing the bubble lifetimes. The
oscillations in pressure are due to density variation between compression to tension, responding to the change of bubble volume. The oscillation time scale is in the range of 10-50 nsec. As the small bubbles collapse, the oscillations in pressure increase and tend to reduce the lifetime of larger bubble. The collapse of the larger bubbles induces even higher pressure oscillations. In fig.(6b) we present for clarity in an expanded time axis the pressure signal and the initial stage of the bubbles expansion as a function of time. The bipolar nature of the stress wave and the initial spread in the bubble radius evolution is presented.

Fig. 5. Pressure/10 and bubble radii with initial values $R_i=0.3, 0.5, 0.7, 1., 1.5 \mu m$ vs time for impurity densities $n_0=10^6 \text{ cm}^{-3}$ for distance of (a) $x=220 \mu m$ and (b) $x=340 \mu m$. 
Fig. 6. Same as fig.(5a) but with: (a) pressure in bar and (b) pressure/10 in a more detailed time scale.

Figure (7) shows the bubble lifetimes as a function of distance x from the free boundary for a laser fluence of 1.53 J/cm² and densities $n_0 = 0$ and $10^6$ cm$^{-3}$. Figure (7) also includes the experimental results obtained in ref.(1). This fluence is consistent with a temperature rise at the free boundary of $\Delta T = 40^ø C$. Comparing the lifetime results for bubbles with initial radius $R_i = 1\mu m$, for $n_0 = 0$ and $n_o = 10^6$ cm$^{-3}$, there is an increase in lifetime from 6 µsec to 10 µsec for $100 < x < 350$ µm. It is clear that impurity interactions have a large influence on the bubble lifetime and should be calculated consistently with the hydrodynamic motion. The lifetime increase from the bubble boundary for, $x < 100$ µm, where the tensile component is low and is screened by the compression component. At larger distances, $x > 350$ µm, the lifetime is again reduced because the tensile component is screened by the void growth. Good agreement is obtained for the bubble lifetimes between our computational results and experimental results of ref.(1) for $n_0 = 10^6$ cm$^{-3}$. 

187
Figure (8) considers the impurity density effect on the bubble lifetimes for bubbles with initial radius \( R_i = 1 \mu m \), for a boundary temperature rise of \( \Delta T_o = 18 \, ^\circ C \) and \( 40 \, ^\circ C \) at a distance \( x = 220 \, \mu m \). For the case \( \Delta T_o = 40 \, ^\circ C \) there is an increase in bubble lifetime with increasing impurity density because of the delay in reaching the constant 1 bar ambient pressure as the impurity density increases. At further higher densities, \( n_o > 5 \cdot 10^6 \), pressure screening and oscillations are strongly increased and the bubble lifetimes are strongly reduced. For smaller \( \Delta T_o = 18 \, ^\circ C \), compare to a fluence of 0.68 \( J/cm^2 \), the bubble lifetimes are shorter and have a much weaker dependence on the impurity density. The results for \( \Delta T_o = 18 \, ^\circ C \) are consistent with the experimental results.\(^1\)

---

**Fig. 7.** Bubbles lifetime vs distance \( x \) for bubbles with initial radius \( R_i = 1.0 \mu m \), \( n_o = 10^6 \, cm^{-3} \) and \( n_o = 0 \). The laser fluence is 1.53 \( J/cm^2 \) and the temperature rise on system boundary is \( \Delta T_o = 40 \, ^\circ C \). The dots are Ref.(1) experimental results.
Fig. 8. Bubbles lifetime vs impurity density $n_0$ for bubbles with initial radius $R_i = 1.0 \ \mu m$, at a distance $x=220 \ \mu m$, boundary temperature rise of $\Delta T_0 = 18 ^\circ C$ and $40 ^\circ C$.

5. CONCLUSIONS

For moderate impurity densities there is strong interaction between the stress wave and the ensemble of evolving voids on a short time scale of stress wave propagation ($\sim 100 \ ns$). The interaction attenuates the stress wave tensile component and induces pressure oscillations. The effect is stronger as the wave propagates inside the system. For low impurity concentration the growing voids interact with each other on a longer time scale ($\sim 10 \mu s$) through the change in the pressure field and strongly influence their lifetimes. Thus bubble evolution, long time before coalescence, should be treated self-consistently with the hydrodynamic pressure in the system and can not be treated as non-interacting bubbles as done in many cases. We found that various types of impurities with different initial radii nucleate voids which evolve on a different time scale. Thus real types of impurity distributions should be considered.

The self-consistent effect of stress wave propagation and void evolution should be tested for different physical effects such as viscosity, strength and failure, and in different types of tissues. More experiments should be done with different concentrations of impurities to verify the interaction between stress wave propagation and bubble evolution.
